Case Report

Introduction: The myocutaneous flap is often used in reconstruction of head and neck defects. However, it is restricted to the middle third of the face. Perforating artery dissection techniques allow further lengthening of the pedicle, thus achieving coverage of the orbitofrontal-parietal region. Case report: A 63-year-old male with a poorly-differentiated invasive squamous cell carcinoma presented with a final defect of 12.0 × 18.0 cm in the right orbitofrontal-parietal region, with dura mater, frontal sinus, and right upper orbit exposure after resection. We designed a pectoralis major flap, with a cutaneous island equaling the defect in dimensions, in the right parasternal region, from the fourth intercostal space to the subcostal region (extended). The pedicle was sectioned after 4 weeks. The coverage was effective, with no major complications, and a satisfactory aesthetic result. Conclusion: This flap can be an excellent option for reconstruction of the upper third of the head when there are limitations to microsurgery.

INTRODUCTION

The pectoralis major myocutaneous flap is often used in reconstruction after head and neck tumor resection. Ariyan et al. first described this technique in 1979.

Few reports have described the use of this flap in reconstruction above the orbits, due to the risk of necrosis and the difficulty of flap mobilization, rotation, and extension.

Defects in the scalp and upper third of the face remain a challenge for surgeons. Advances in surgery have included use of perforating arteries and improved techniques of dissection of the pectoral pedicle. These have allowed release and lengthening of the pectoralis major muscle, augmentation of its arc of rotation, and gain in the extension of the flap (cutaneous island) to obtain more distal coverage in the head and upper third of the face.

OBJECTIVE

This study reported the use of an extended pedicled muscle flap to cover defects in the right orbitofrontal-parietal region after resection of invasive squamous cell carcinoma.

CASE REPORT

A 63-year-old male with an ulcerated, grade III, poorly-differentiated squamous cell carcinoma presented 6 months after initial resection and grafting with a recurrent tumor in the right parietal region. The patient had a 5.0-cm right parietal ulcerated lesion with an adjacent osteolytic component, another frontal lesion measuring 3.0 cm, and another 4.0-cm lesion in the right lower frontal region with signs of adjacent bone involvement. Invasion of the paranasal sinus and right superomedial orbit had occurred (Figure 1).

The case was evaluated by the oncological surgery and neurosurgery teams of the Guilherme Álvaro Hospital, Santos, SP, for tumor resection with curative intention, in collaboration with the plastic

surgery team for immediate reconstruction. The lesion was resected with lateral margins of 15 mm, with resection of the affected bone in the parietal and upper frontal regions and anterior and posterior walls of the right frontal sinus, leaving the dura mater exposed.

The superomedial bony portion of the right orbit was resected, revealing communication with the right frontal sinus and right nasal cavity; the globe, ocular muscles, and 1.0 cm of the upper eyelid were preserved. The final defect measured 12.0 × 18.0 cm in the right orbitofrontal-parietal region, with dura mater, frontal sinus, and right upper orbit exposure (Figure 2).

For reconstruction, we marked a pectoralis major flap measuring 12.0 × 18.0 cm in the right parasternal area, from the fourth intercostal space to the subcostal region (extended), to enable coverage of the defect without lateral traction on the head (Figure 3).

We detached the pectoralis muscle, while preserving the thoracoacromial pedicle, leaving only a long muscular band in the axis of the vascular pedicle, and performed total section of the muscle at the base of the flap; a cutaneous band on the pedicle was left for protection and maintenance of the perforating cutaneous thoracoacromial pedicle.

We performed total section of the superior pectoral nerve, partial section of the deltoid muscle insertion in the clavicle to reduce rotation tension in the external pedicle, and released the vascular pedicle to the thoracoacromial trunk at the origin of the axillary artery. The closure of the donor area was performed with tension-free advancement flaps (Figure 4).

To obliterate the frontal-orbital-nasal communication, a contralateral frontal muscle flap was created and sutured in place.

During recovery, the patient developed a 3.0-cm necrotic area at the distal edge of the flap; this was resected together with the pedicle 4 weeks later. Wet dressings were applied to the area of resected necrosis until granulation tissue was observed, with subsequent grafting. The coverage was effective, with no major complications or hematomas, and a satisfactory aesthetic result was achieved despite the extensive oncologic surgery. The patient remains under follow-up, and is receiving radiotherapy because of high risk of recurrence and infiltration of the dura mater and frontal sinus mucosa (Figure 5).

DISCUSSION

The pectoralis major flap is commonly used for head and neck reconstruction, but its applicability in the supraorbital area has a risk of failure and necrosis due to tension. Its use depends largely on patient anatomy. The cutaneous island on the pectoralis muscle typically measures 6.0 × 12.0 cm. The skin flap should not be extended more than 20% beyond the edge of
Extended and pedicled pectoralis major flap for right orbitofrontal-parietal reconstruction

The extended pedicle flap was an excellent surgical option for reconstruction of the upper third of the head following extensive tumor resection, in an area with limitations to microsurgery; with anatomical knowledge and careful dissection, we obtained a satisfactory result.

the muscle². This type IV flap with a thoracoacromial dominant pedicle is easy to monitor and dissect.

Most reports on this flap discuss a musculocutaneous or muscular type, with a mostly minor complication rate of 33% and a 2% risk of necrosis³.

Cadaver studies by Rikimaru et al.⁴,⁵ identified the main cutaneous perforating arteries of the second and third intercostal area using microvascular angiography. Based on these studies, Nishi et al.⁶ described flaps using pectoral and deltopectoral perforating arteries.

Zhang et al.⁷ described a pectoral region flap in an anatomical study of the perforating branches of the thoracoacromial artery, and reported the existence of 1 or 2 main perforators within 4.0 cm of the point of union of the acromiotoracic and midclavicular lines. These perforators allowed a pedicle flap using thoracoacromial artery perforators to be performed. This flap can be performed with microsurgical technique for superior defects⁸-¹⁰.

With this anatomical knowledge of the perforators of the thoracoacromial vascular pedicle, a large cutaneous island can be maintained, and the muscle can be partially or totally resected. The flap rotation arc may improve with muscle detachment, careful dissection of the pedicle, and section of deltoïd muscle bands, and infraclavicular tunneling has been described. Surgery is ideally performed in a single session, but an external pedicle is needed to obtain coverage distant from the donor bed, as in the present case. The literature to date has not reported a pedicled pectoralis major flap that has been extended this far while remaining viable.
